MARKOV CHAINS WITH RARE TRANSITIONS AND SIMULATED ANNEALING¹John N. Tsitsiklis²

ABSTRACT

We consider Markov chains in which the entries of the one-step transition probability matrix are known to be of different orders of magnitude and whose structure (that is, the orders of magnitude of the transition probabilities) does not change with time. For such Markov chains we present a method for generating order of magnitude estimates for the t -step transition probabilities, for any t . We then notice that algorithms of the simulated annealing type may be represented by a Markov chain which is approximately stationary over fairly long time intervals. Using our results we obtain a characterization of the convergent "cooling" schedules for the a general class of algorithms of the simulated annealing type.

I. INTRODUCTION.

The main objective of this paper is the characterization of the cooling schedules under which a simulated annealing algorithm converges to a set of desired states, such as the set where some cost function is minimized. In particular, thus generalizing the results of Hajek [9]. The method we follow is based on the observation that in simulated annealing algorithms the "temperature" remains approximately constant for sufficiently long times. For this reason, we may exploit bounds and estimates which are valid for singularly perturbed (approximately) stationary Markov chains and obtain interesting conclusions for the simulated annealing algorithm. In the course of developing our result on simulated annealing we derive certain results on approximately stationary singularly perturbed Markov chains which seem to be of independent interest.

The structure of the paper is the following. In Section 2 we assume that we are dealing with a Markov chain in which each of the one-step transition probabilities is roughly proportional to a certain power of ϵ , where ϵ is a small parameter. We then present an algorithm, consisting of the solution of certain shortest path problems and some graph theoretic manipulations, which provides estimates for the transition probabilities of the Markov chain for any time between 0 and $1/\epsilon$. Then, in Section 3, we indicate how the procedure of Section 2 may be applied recursively to produce similar estimates on the transition probabilities for all times. In Section 4 we use the results of Section 3 to characterize the convergence of the simulated annealing algorithm.

II. MARKOV CHAINS PARAMETRIZED BY A SMALL PARAMETER.

In this Section we derive order of magnitude estimates on the transition probabilities of a non-stationary Markov chain. Our results are based on the assumption that such order of magnitude information is available on the one-step transition probabilities of the Markov chain.

We start with some notation. We use \mathcal{N} and \mathcal{N}_0 to denote the positive and the nonnegative integers, respectively. We also let \mathcal{U} denote the set of functions $f:(0, \infty) \mapsto (0, \infty)$ such that for every $n \in \mathcal{N}_0$ there exists some $c_n > 0$ such that $f(\epsilon) \leq c_n \epsilon^n$, $\forall \epsilon > 0$. Notice that \mathcal{U} has the property that $f(\epsilon)/\epsilon^n \in \mathcal{U}$, $\forall f \in \mathcal{U}$, $\forall n \in \mathcal{N}$. Also notice that $c^{1/\epsilon} \in \mathcal{U}$, for any $c \in (0, 1)$.

We consider a (generally non-stationary) finite state, discrete time Markov chain $X = \{x(t): t \geq 0\}$ with state space $\{1, \dots, N\}$. For any $t \geq 0$ we let $q_{ij}(t) = P(x(t+1) = j | x(t) = i)$ and $p_{ij}(t) = P(x(t) = j | x(0) = i)$. We assume that some structural information is available on this Markov chain. More precisely, let there be given a collection $\mathcal{A} = \{\alpha_{ij}: 1 \leq i, j \leq N\}$ of elements of $\mathcal{N}_0 \cup \{\infty\}$. Let $f \in \mathcal{U}$ and let C_1, C_2 be positive constants. We assume that for some $\epsilon > 0$ we have

$$C_1 \epsilon^{\alpha_{ij}} \leq q_{ij}(t) \leq C_2 \epsilon^{\alpha_{ij}}, \quad \forall t \geq 0, \quad \text{if } \alpha_{ij} < \infty, \quad (2.1)$$

$$0 \leq q_{ij}(t) \leq f(\epsilon), \quad \forall t \geq 0, \quad \text{if } \alpha_{ij} = \infty. \quad (2.2)$$

We call \mathcal{A} the structure of the Markov chain X . We make the following assumption on \mathcal{A} :

$$\alpha_{ik} \leq \alpha_{ij} + \alpha_{jk}, \quad \forall i, j, k. \quad (2.3)$$

We shall discuss later how this assumption may be removed. For the rest of this section we assume that \mathcal{A}, C_1, C_2, f are fixed and we denote by $\mathcal{M}_\epsilon(\mathcal{A}, C_1, C_2, f)$ the set of Markov chains for which (2.1) and (2.2) hold. (Occasionally we use the shorter notation \mathcal{M}_ϵ , provided that no confusion may arise.)

We classify the states in the state space by considering a Markov chain in which only those transitions from i to j with $\alpha_{ij} = 0$ are allowed. In particular, a state i is called **transient** if there exists some state j such that $\alpha_{ij} = 0$ and $\alpha_{ji} > 0$. Otherwise i is called **recurrent**. In view of assumption (2.3), this is equivalent to the conventional definition. Let TR, R denote the sets of transient and recurrent states, respectively. For any $i \in R$, we let $R_i = \{j: \alpha_{ij} = 0\}$. We then have $j \in R_i$ if and only if $j \in R$ and $i \in R_j$; we thus obtain the usual partition of the set of recurrent states into ergodic classes. Also, notice that, for any $i \in TR$, there exists some $j \in R$ such that $\alpha_{ij} = 0$.

Our first result provides order of magnitude estimates on the probability that a recurrent state j is the first state to be visited, starting from a transient state i . We use the notation $T = \min\{t \geq 0: x(t) \in R\}$. We also use the convention that $\epsilon^\infty = 0$.

Proposition 2.1: There exist $F > 0$ and $g \in \mathcal{U}$ such that for any $\epsilon > 0, X \in \mathcal{M}_\epsilon, i \in TR, j \in R$ we have

$$C_1 \epsilon^{\alpha_{ij}} \leq P(x(T) = j | x(0) = i) \leq F \epsilon^{\alpha_{ij}} + g(\epsilon). \quad (2.4)$$

Proof: Let us fix some $j \in R$. We define, for $\alpha \in \mathcal{N}_0 \cup \{\infty\}$, $S_\alpha = \{i \in TR: \alpha_{ij} = \alpha\}$ and $Q_\alpha = \{i \in TR: \alpha_{ij} \geq \alpha\}$. We then define $p_{\alpha, \epsilon} = \sup_{X \in \mathcal{M}_\epsilon} \max_{i \in Q_\alpha} P(x(T_1) = j | x(0) = i)$. We first prove, by induction on α , that for any $\alpha < \infty$ there exists some $F_\alpha > 0$ such that $p_{\alpha, \epsilon} \leq F_\alpha \epsilon^\alpha, \forall \epsilon > 0$. This is clearly true for $\alpha = 0$. Suppose it is true for all α less than some positive integer β . Let $i \in Q_\beta$ and $X \in \mathcal{M}_\epsilon$. Notice that for any state k we have $\alpha_{ik} + \alpha_{kj} \geq \alpha_{ij} \geq \beta$. Using (2.1) and the induction hypothesis we obtain

$$P(x(T) = j | x(0) = i) \leq \sum_{\alpha=0}^{\beta-1} \sum_{k \in S_\alpha} P(x(T) = j | x(1) = k) P(x(1) = k | x(0) = i) +$$

$$+ P(x(1) \in Q_\beta | x(0) = i) \max_{l \in Q_\beta} P(x(T) = j | x(1) = l) + P(x(1) = j | x(0) = i) \leq$$

$$\sum_{\alpha=0}^{\beta-1} \sum_{k \in S_\alpha} F_\alpha \epsilon^{\alpha k} C_2 \epsilon^{\alpha k} + (1 - C_1) p_{\beta, \epsilon} + C_2 \epsilon^\beta \leq$$

$$[N \max_{\alpha < \beta} \{F_\alpha\} C_2 + C_2] \epsilon^\beta + (1 - C_1) p_{\beta, \epsilon}.$$

Taking the supremum of the left hand side over all $i \in Q_\beta$ and all $X \in M_\epsilon$, we obtain, for some constant F ,

$$p_{\beta, \epsilon} \leq F \epsilon^\beta + (1 - C_1) p_{\beta, \epsilon}$$

from which it follows that the induction hypothesis is also true for $\beta + 1$.

Finally, we assume that $i \in S_\infty$. Then,

$$P(x(T) = j | x(0) = i) \leq$$

$$P(x(1) \in TR, x(1) \notin S_\infty | x(0) = i) + P(x(1) = j | x(0) = i) + P(x(1) \in S_\infty | x(0) = i) p_{\infty, \epsilon} \leq$$

$$N f(\epsilon) + (1 - C_1) p_{\infty, \epsilon}.$$

Thus, $p_{\infty, \epsilon} \leq (N/C_1) f(\epsilon)$, $\forall \epsilon > 0$. This completes the proof of the second inequality in (2.4). The first inequality is a trivial consequence of (2.1). •

Let us mention another method for proving Proposition 2.1. We could first prove it for stationary Markov chains in M_ϵ , because in this case there are explicit formulae for the absorption probabilities. (Such a result is obtained in [12].) Then, we notice that $p_{\alpha, \epsilon}$ is bounded above by the absorption probabilities which would result if an adversary was allowed to choose $q_{ij}(t)$ at each time t after observing the current state, subject to the constraints (2.1) and (2.2). It follows from standard results in Markovian decision theory that the optimal policy for the adversary is a stationary one and therefore the bounds obtained for stationary Markov chains also apply to the nonstationary ones. Unfortunately, this method does not seem to work for our subsequent results because they correspond to a maximization over a finite horizon for which stationary policies are not in general optimal.

Let us also point out that Proposition 2.1 is false if the assumption (2.3) is removed.

The main result of this section is based on the following algorithm which provides important structural information on the long run behavior of Markov chains in M_ϵ .

Algorithm: (Input: $A = \{\alpha_{ij}; 1 \leq i, j \leq N\}$ and R ; Output: $V = \{V(i, j); 1 \leq i, j \leq N\}$)

1. Let $c_{ij} = \alpha_{ij} - 1$, if $i \in R, j \in R, j \notin R_i$ and $c_{ij} = \alpha_{ij}$, otherwise. (Notice that $c_{ij} \geq 0$ always holds.)
2. Solve the shortest path problem from any origin $i \in R$ to any destination $j \in R$, with respect to the link lengths c_{ij} and subject to the constraint that any intermediate state on a path must be an element of R . For example, the Bellman algorithm may be used: $V_0(i, j) = 0$, if $i = j$; $V_0(i, j) = \infty$, if $i \neq j$ and

$$V_{n+1}(i, j) = \min_{k \in R} \{V_n(i, k) + c_{kj}\}. \quad (2.5)$$

Let $V(i, j)$ be the length of the shortest path (which is obtained after at most N stages of the Bellman algorithm suggested above).

3. If $i \in R, j \in TR$, let

$$V(i, j) = \min_{k \in R} \{V(i, k) + c_{kj}\} = \min_{k \in R} \{V(i, k) + \alpha_{kj}\}. \quad (2.6)$$

4. If $j \in TR$, let

$$V(i, j) = \min_{k \in R} \{c_{ik} + V(k, j)\} = \min_{k \in R} \{\alpha_{ik} + V(k, j)\}. \quad (2.7)$$

Notice that the output $V(i, j)$ of the above algorithm may be interpreted as the length of the shortest path from i to j subject to the constraint that all states on the path belong to R , except possibly for the first and the last one. We continue with a few elementary observations on this algorithm:

Proposition 2.2: (i) $V(i, j) \geq 0, \forall i, j$.

(ii) $V(i, j) \geq 1, \forall i, \forall j \in TR$.

(iii) $V(i, j) \leq V(i, k) + V(k, j), \forall i, j, k$.

(iv) If $j \in R$ and $j' \in R_j$, then $V_n(i, j) = V_n(i, j'), \forall i, n$. Also, If $i \in R$ and $i' \in R_i$, then $V_n(i, j) = V_n(i', j), \forall j, n$.

Proof: Part (i) follows from the shortest path interpretation and the nonnegativity of the c_{ij} 's. Part (ii) follows from (2.6) and the fact that $\alpha_{kj} \geq 1$, whenever $k \in R$ and $j \in TR$. Part (iii) is clearly true for $k \in R$, due to the shortest path interpretation. So, assume that $k \in TR$. Let us take shortest paths from i to k (of length $V(i, k)$) and from k to j (of length $V(k, j)$) and concatenate them. This produces a path from i to j , of length $V(i, k) + V(k, j)$, such that all intermediate states, except from k , belong to R . If k_1 and k_2 are the predecessor and the successor, respectively, of k in this path, we use (2.3) to conclude that $c_{k_1 k} + c_{k k_2} \geq c_{k_1 k_2}$ which shows that k may be eliminated from this path, to produce a path from i to j , with all intermediate elements belonging to R , and

with length less or equal than $V(i, k) + V(k, j)$, as desired. Finally, for part (iv), we use assumption (2.3) to see that $c_{ij} = \alpha_{ij} = 0$, whenever $i \in R$ and $j \in R_i$. The result follows from the shortest path interpretation. •

We notice that, as a consequence of part (iv) of the proposition, the algorithm need not be carried out for all states. It suffices to consider transient states and one representative from each ergodic class R_i .

The following proposition establishes the relevance of the $V(i, j)$'s to the Markov chains under study.

Proposition 2.3: For any $C_3 > 0$, there exist positive constants G_1, G_2, G_3, G_4 , with $G_4 < 1$, and some $g \in \mathcal{U}$ such that, for any $\epsilon > 0$, for any Markov chain in \mathcal{M}_ϵ and any states i, j we have

$$G_1(\epsilon(t - N))^N \epsilon^{V(i, j)} \leq p_{ij}(t) \leq G_2 \epsilon^{V(i, j)} + \chi_i G_3 G_4^t \epsilon^{\alpha_{ij}} + g(\epsilon), \quad \forall t \in [N, C_3/\epsilon], \quad (2.8)$$

where $\chi_i = 0$, if $i \in R$, and $\chi_i = 1$, otherwise. (The upper bound in (2.8) is also true for $t \in [1, N]$.) In particular, there exist $G_1 > 0, G_2 > 0, g \in \mathcal{U}$ such that

$$G_1 \epsilon^{V(i, j)} \leq p_{ij}(\frac{1}{\epsilon}) \leq G_2 \epsilon^{V(i, j)} + g(\epsilon). \quad (2.9)$$

Proof: Notice that for any $i \in R, j \notin R_i$ we have $q_{ij}(t) \leq C_2 \epsilon, \forall t$. It follows that $P(x(t+1) \notin R_j | x(t) \in R_j) \leq NC_2 \epsilon$, from which we easily conclude that there exists some $F_1 > 0$ such that

$$P(x(t) \in R_i | x(s) \in R_i) \geq F_1, \quad 0 \leq s \leq t \leq C_3/\epsilon, \quad \forall \epsilon > 0, \forall X \in \mathcal{M}_\epsilon, \forall i \in R. \quad (2.10)$$

We now start the proof of the lower bound in (2.8). If $V(i, j) = \infty$, there is nothing to prove, so we will be assuming that $V(i, j) < \infty$. We first assume that $i \in R$ and $j \in R$. Then, there exists a sequence $i = i_1, i_2, \dots, i_n = j$ of elements of R , (with $n \leq N$) such that $\sum_{k=1}^{n-1} c_{i_k, i_{k+1}} = V(i, j)$ and such that $\alpha_{i_k, i_{k+1}} \geq 1, \forall k$. Let $k \in \mathcal{N}$ and suppose that there exists some $F_k > 0$ such that, for all $\epsilon > 0$ and for all $X \in \mathcal{M}_\epsilon$,

$$P(x(t) \in R_{i_k} | x(0) = i) \geq F_k (\epsilon(t - k + 1))^{k-1} \epsilon^{\sum_{l=1}^{k-1} c_{i_l, i_{l+1}}}, \quad \forall t \in [k-1, C_3/\epsilon]. \quad (2.11)$$

We then have

$$P(x(t) \in R_{i_{k+1}} | x(0) = i) \geq \sum_{s=0}^{t-1} P(x(t) \in R_{i_{k+1}} | x(s+1) \in R_{i_{k+1}}) P(x(s+1) \in R_{i_{k+1}} | x(s) \in R_{i_k}) P(x(s) \in R_{i_k} | x(0) = i) \geq$$

$$\sum_{s=k}^{t-1} \left(F_k (\epsilon(s-k+1))^{k-1} \epsilon^{\sum_{i=1}^{k-1} c_{i,i+1}} \right) C_1 \epsilon^{\alpha_{k,k+1}} F_2 \geq (F_k F_2 C_1) \epsilon^{\sum_{i=1}^k c_{i,i+1}} \sum_{s=k}^{t-1} (\epsilon(s-k+1))^{k-1}. \quad (2.12)$$

Clearly, there exists a constant F'_k such that

$$\sum_{s=k}^{t-1} (s-k+1)^{k-1} \geq F'_k (t-k)^k, \quad \forall t.$$

Inequality (2.10) shows that (2.11) holds for $k = 1$. We have thus proved by induction on k that (2.11) holds for all k . Notice that

$$P(x(t) = j | x(0) = i) \geq P(x(t) = j | x(t-1) \in R_j) P(x(t-1) \in R_j | x(0) = i) \geq$$

$$C_1 P(x(t-1) \in R_j | x(0) = i),$$

which completes the proof of the left hand side of (2.8), for the case where $i \in R$ and $j \in R$.

Suppose now that $i \in R$, $j \in TR$ and let $k \in R$ be such that $V(i, j) = V(i, k) + \alpha_{kj}$. If $\alpha_{kj} = \infty$, then $V(i, j) = \infty$ and there is nothing to prove. So, assume that $\alpha_{kj} < \infty$. Then,

$$P(x(t) = j | x(0) = i) \geq P(x(t) = j | x(t-1) = k) P(x(t-1) = k | x(0) = i) \geq$$

$$C_1 \epsilon^{\alpha_{kj}} P(x(t-1) = k | x(0) = i).$$

Given that we have already proved the lower bound for $p_{ik}(t)$, the desired result for $p_{ij}(t)$ follows.

Finally, let $i \in TR$. The result follows similarly by choosing $k \in R$ so that $\alpha_{ik} + V(k, j) = V(i, j)$ and using the inequality

$$P(x(t) = j | x(0) = i) \geq P(x(1) = k | x(0) = i) P(x(t) = j | x(1) = k).$$

We now turn to the proof of the upper bound in (2.8). Let $i \in R$ be fixed. We define $E_\alpha = \{j \in R: V(i, j) = \alpha\}$, $T_\alpha = \{j \in TR: V(i, j) = \alpha\}$, $E_{\leq \alpha} = \cup_{\beta \leq \alpha} E_\beta$. We also define similarly $E_{\geq \alpha}$, $T_{\leq \alpha}$, $T_{\geq \alpha}$. We will prove by induction that for any $\alpha < \infty$ the following statements hold:

(SE_α): There exists some G_α such that $\forall \epsilon > 0$, $\forall X \in \mathcal{M}_\epsilon$, $\forall j \in E_{\geq \alpha}$ and $\forall t \leq C_3/\epsilon$ we have $p_{ij}(t) \leq G_\alpha \epsilon^\alpha$.

(ST_α): There exists some G'_α such that $\forall \epsilon > 0$, $\forall X \in \mathcal{M}_\epsilon$, $\forall j \in T_{\geq \alpha}$ and $\forall t \leq C_3/\epsilon$ we have $p_{ij}(t) \leq G'_\alpha \epsilon^\alpha$.

Statement SE_0 is trivially true, with $G_\alpha = 1$. We now prove ST_1 . (Notice that $T_{\geq 1} = TR$.)

Now,

$$P(x(t+1) \in TR | x(0) = i) \leq$$

$$P(x(t+1) \in TR | x(t) \in TR) P(x(t) \in TR | x(0) = i) + P(x(t+1) \in TR | x(t) \in R) \leq$$

$$(1 - C_1)P(x(t) \in TR | x(0) = i) + NC_2\epsilon. \quad (2.13)$$

Since $i \in R$, $P(x(0) \in TR | x(0) = i) = 0$ and (2.13) implies $P(x(t) \in TR | x(0) = i) \leq (NC_2\epsilon)/C_1$, $\forall t \geq 0$, which proves ST_1 .

Now let α be some positive integer and assume that statements $SE_{\beta-1}$ and ST_β are true, for all $\beta \leq \alpha$. We will prove that SE_α and $ST_{\alpha+1}$ are also true. We first need the following Lemma.

Lemma 2.1: If $j \in J = E_{\leq(\alpha-1)} \cup T_{\leq\alpha}$ and $k \in K = E_{\geq\alpha} \cup T_{\geq(\alpha+1)}$, then $V(i, j) + \alpha_{jk} \geq \alpha + 1$.

Proof: (i) If $j \in E_{\leq(\alpha-1)}$, $k \in E_{\geq\alpha}$, then $V(i, j) + \alpha_{jk} = V(i, j) + c_{jk} + 1 \geq V(i, k) + 1 \geq \alpha + 1$.

(ii) If $j \in E_{\leq(\alpha-1)}$, $k \in T_{\geq(\alpha+1)}$, then $V(i, j) + \alpha_{jk} = V(i, j) + c_{jk} \geq V(i, k) \geq \alpha + 1$.

(iii) If $j \in T_{\leq\alpha}$, $k \in E_{\geq\alpha}$, let $l \in R$ be such that $V(i, l) + \alpha_{lj} = V(i, j)$. Suppose that $l \in R_k$. Then, $V(i, l) = V(i, k) \geq \alpha$ and $V(i, j) = V(i, l) + \alpha_{lj} \geq \alpha + 1$, which contradicts the assumption $j \in T_{\leq\alpha}$. We thus assume that $l \notin R_k$. Then, $V(i, j) + \alpha_{jk} = V(i, l) + \alpha_{lj} + \alpha_{jk} \geq V(i, l) + \alpha_{lk} = V(i, l) + c_{lk} + 1 \geq V(i, k) + 1 \geq \alpha + 1$.

(iv) If $j \in T_{\leq\alpha}$, $k \in T_{\geq(\alpha+1)}$, let $l \in R$ be such that $V(i, l) + \alpha_{lj} = V(i, j)$. Then, $V(i, j) + \alpha_{jk} = V(i, l) + \alpha_{lj} + \alpha_{jk} \geq V(i, l) + \alpha_{lk} \geq V(i, k) \geq \alpha + 1$. •

We now use the induction hypothesis and Lemma 2.1 to obtain

$$P(x(t+1) \in K | x(t) \in J) P(x(t) \in J | x(0) = i) \leq$$

$$\sum_{k \in K, j \in J} P(x(t+1) = k | x(t) = j) P(x(t) = j | x(0) = i) \leq$$

$$\sum_{k \in K, j \in J} C_2 \epsilon^{\alpha_{jk}} G \epsilon^{V(i, j)} \leq (N^2 C_2 G) \epsilon^{\alpha+1},$$

where $G = \max\{G_{\beta-1}, G'_\beta; \beta \leq \alpha\}$. It follows that

$$P(x(t) \in K | x(0) = i) \leq (N^2 C_2 G) \epsilon^{\alpha+1} C_3 / \epsilon, \quad \forall t \in [1, C_3 / \epsilon],$$

which proves SE_α . Finally,

$$P(x(t+1) \in T_{\geq\alpha+1} | x(0) = i) \leq (1 - C_1)P(x(t) \in T_{\geq\alpha+1} | x(0) = i) + NG_\alpha \epsilon^\alpha C_2 \epsilon + N^2 C_2 G \epsilon^{\alpha+1}$$

which shows that

$$P(x(t) \in T_{\geq \alpha+1} | x(0) = i) \leq (1/C_1)(NG_\alpha C_2 + N^2 C_2 G) \epsilon^{\alpha+1}, \quad \forall t \in [1, C_3/\epsilon].$$

This proves ST_α and completes the induction.

We have thus completed the proof of the upper bound in (2.9) for the case where $i \in R$ and $V(i, j) < \infty$. The proof for the case $i \in R$ and $V(i, j) = \infty$ is very simple and is omitted. We now assume that $i \in TR$. Let T be the random time of Proposition 2.1. Then, for some $F > 0$, $G > 0$, $g, g', g'' \in \mathcal{U}$, we have

$$\begin{aligned} p_{ij}(t) &\leq \\ P(T > t) + \sum_{k \in R} P(x(t) = j | x(T) = k, T \leq t) P(x(T) = k, T \leq t | x(0) = i) P(T \leq t | x(0) = i) &\leq \\ (1 - C_1)^{1/t} + \sum_{k \in R} [G \epsilon^{V(k, j)} + g(\epsilon)] [F \epsilon^{\alpha_{ik}} + g'(\epsilon)] &\leq \\ (1 - C_1)^{1/t} + NGF \epsilon^{V(i, j)} + g''(\epsilon), &\quad \forall t \in [1, C_3/\epsilon]. \end{aligned}$$

This completes the proof of the proposition. •

Notice that the upper and lower bounds are tight, within a multiplicative constant independent of ϵ , when $t = 1/\epsilon$. For smaller times the bounds are much further apart. It is not hard to close this gap, although we do not need to do this for our purposes. In particular, the exponent in the term $(\epsilon(t - N + 1))^N$ in the lower bound may be reduced. This may be accomplished with a minor modification of the induction hypothesis in the proof of the lower bound. The upper bound may be also improved in a similar manner.

The remainder of this section is devoted to showing that the assumption (2.3) on the structure of the Markov chains under study is not an essential restriction. Roughly speaking, we will establish that our results are applicable to any Markov chain which is aperiodic in the fastest time scale in a strong sense to be defined below.

Let there be given a set of nonnegative integers $\mathcal{A} = \{\alpha_{ij} : 1 \leq i, j \leq N\}$, not necessarily satisfying (2.3). Let us define β_{ij} as the length of the shortest path from i to j , with respect to the link lengths α_{ij} . (we require a "path" to have at least one hop; thus, $\beta_{ii} \neq 0$, in general.) We make the following assumption on \mathcal{A} :

Assumption AP: There exists some positive integer M with the following property: for any $m \geq M$ and for any i such that $\beta_{ii} = 0$, there exists a path (i_1, i_2, \dots, i_m) such that $i_1 = i_m = i$ and which has zero length (with respect to the link lengths α_{ij}).

For any Markov chain whose structure is described by \mathcal{A} , meaning that the estimates (2.1), (2.2) are valid, assumption AP requires the following: if we substitute 0 for ϵ , and decompose the resulting Markov chain into ergodic classes, in the usual manner, then each of the non communicating classes of recurrent states is aperiodic. However, this requirement is not sufficient for Assumption AP to hold.

It can be shown that if \mathcal{A} satisfies assumption AP, then M can be chosen to be smaller than N^2 . (This is related to the fact that the "index of primitivity" of any primitive nonnegative matrix is bounded above by $N^2 - 2N + 2$; for more details, see Chapter 2 of [13].)

Now suppose that \mathcal{A} satisfies assumption AP and let M be as prescribed in that assumption. Given some positive constants C_1, C_2 , some $f \in \mathcal{U}$ and some $\epsilon > 0$, consider the set $M_\epsilon(\mathcal{A}, C_1, C_2, f)$. Let Q be some positive integer. For any $X \in M_\epsilon(\mathcal{A}, C_1, C_2, f)$, let us define X^Q to be the discrete time Markov chain obtained by sampling X every Q time units. Finally, let $\beta = \{\beta_{ij}; 1 \leq i, j \leq N\}$. Due to their definition as shortest path lengths, the coefficients β_{ij} satisfy (2.3). The following Proposition establishes that the coefficients β_{ij} describe the structure of the sampled Markov chain X^Q , at least when the sampling period Q is chosen large enough.

Proposition 2.5: Suppose that \mathcal{A} satisfies Assumption AP. Then, there exists some $Q > 0$, some positive C'_1, C'_2 and some $f' \in \mathcal{U}$ such that $\{X^Q; X \in M_\epsilon(\mathcal{A}, C_1, C_2, f)\}$ is a subset of $M_\epsilon(\beta, C'_1, C'_2, f')$.

Proof: Let $B = \max\{\beta_{ij}; \beta_{ij} < \infty\}$ and $Q = \max\{N(B+2), M+2N\}$, where M is the constant of Assumption AP. Let us fix some i, j . Consider an arbitrary sequence of Q transitions from i to j . The probability that this sequence occurs is bounded above by $C_2^Q \epsilon^{\beta_{ij}}$. There are less than N^Q such sequences. Hence, $P(x^Q(1) = j | x^Q(0) = i) \leq N^Q C_2^Q \epsilon^{\beta_{ij}}$, which shows that X^Q satisfies the right hand side inequality of (2.1), with C_2 replaced by $C'_2 = (NC_2)^Q$ and with α_{ij} replaced by β_{ij} .

In order to show that the left hand side inequality in (2.1) also holds for the Markov chain X^Q , it is sufficient to produce a sequence of exactly Q transitions leading from i to j for which the total length (w.r.t. α_{ij}) is less or equal than β_{ij} . This is vacuously true if $\beta_{ij} = \infty$; we thus assume that $\beta_{ij} < \infty$. We proceed as follows: find some path from i to j of length β_{ij} . Then find some k which appears on this path at least $(B+2)$ times. (Such a k exists because $Q \geq N(B+2)$.) Then, $B \geq \beta_{ij} \geq (B+1)\beta_{kk}$, which shows that $\beta_{kk} = 0$. Now, find a path from i to k with length equal to β_{ik} , as well as a path from k to j with length β_{kj} . Let n_1, n_2 be the number of hops in these paths, respectively. Without loss of generality, we may assume that $n_1 < N$ and $n_2 < N$. Then, find a path from k to k (i.e. a cycle) which has zero length and exactly $Q - n_1 - n_2$ hops. (This is

possible due to Assumption AP and because $Q - n_1 - n_2 \geq Q - 2N \geq M$). Finally, merge the three paths to obtain a path from i to j with length β_{ij} and with exactly Q hops. •

Using the above result, Proposition 2.3 becomes applicable to an appropriately sampled version of a given Markov chain, assuming condition AP. We notice that Proposition 2.3 will provide us with estimates of the transition probabilities only for those times which are integer multiples of Q . However, it is easy to show that the same estimates are also valid for intermediate times as well.

Using a more complicated reduction procedure it is possible to apply an appropriately modified version of Proposition 2.3 to all discrete Markov chains, including periodic ones.

We close this section by pointing out that there is nothing special about the coefficients α_{ij} being integer. For example, if the α_{ij} are rationals we could introduce another small parameter δ (to replace ϵ) and another set of integer coefficients β_{ij} , so that $\delta^{\beta_{ij}} = \epsilon^{\alpha_{ij}}$. Even if the α_{ij} 's are not rational, neither are their ratios rational, the proof of Proposition 2.3 remains valid, as long as $\min\{\alpha_{ij}\} \geq 1$. This can be always achieved by redefining the small parameter ϵ .

III. DETERMINING THE STRUCTURE AT SUCCESSIVELY SLOWER TIME SCALES.

Proposition 2.3 allows us to determine the structure of a Markov chain $X \in \mathcal{M}_\epsilon$ in the first of the slow time scales, that is for times of the order of $1/\epsilon$. However, we notice that the transition probabilities $P(x(1/\epsilon) = j | x(0) = i)$ satisfy (2.1), (2.2), (with a new choice of C_1, C_2, f) provided that we replace α_{ij} by $V(i, j)$. Moreover, due to part (iii) of Proposition 2.2, the coefficients $V(i, j)$ satisfy the triangle inequality (2.3) and, therefore, Proposition 2.3 becomes applicable once more. This yields estimates for the transition probabilities $P(x(1/\epsilon^2) = j | x(0) = i)$. This procedure may be repeated to yield estimates for $P(x(1/\epsilon^d) = j | x(0) = i)$, for any positive integer d . To summarize, we have the following algorithm:

Algorithm II: (Input: $A = \{\alpha_{ij}: 1 \leq i, j \leq N\}$, satisfying (2.3); Output: for each $d \in \mathcal{N}_0$, a collection $V^d = \{V^d(i, j): 1 \leq i, j \leq N\}$ and a subset R^d of the state space.)

1. Let $V^0(i, j) = \alpha_{ij}, \forall i, j$.
2. Having computed V^d , let R^d be the set of all states such that $V^d(i, j) = 0$ implies $V^d(j, i) = 0$. (TR^d will denote the complement of R^d and, for any $i \in R^d$, let $R_i^d = \{j \in R^d: V^d(i, j) = 0\}$.)
3. Let V^d, R^d be the input to Algorithm I; let V^{d+1} be the output returned by Algorithm I.

The remarks preceding Algorithm II establish the the next proposition. (Notice that when we use Proposition 2.3 to obtain estimates for $t \approx 1/\epsilon^d$, the unit of time becomes $1/\epsilon^{d-1}$. For this reason, the variable t in Proposition 2.3 must be replaced by $t\epsilon^{d-1}$.)

Proposition 3.1: Given some A satisfying (2.3) and some $d \in \mathcal{N}$, let $V^d(i, j), R^d$, be the collection of integers and the subset returned by Algorithm II. Then, for any positive constants C_1, C_2 and for any $f \in \mathcal{U}$, there exist positive constants $D_1, D_2, D_3, D_4 < 1$ and $g \in \mathcal{U}$, such that, for any $\epsilon > 0$ and for any Markov chain $X \in \mathcal{M}_\epsilon(A, C_1, C_2, f)$ we have

$$D_1(\epsilon(\epsilon^{d-1}t - N))^N \epsilon^{V^d(i, j)} \leq P(x(t) = j | x(0) = i) \leq D_2 \epsilon^{V^d(i, j)} + \chi_i D_3 D_4^{t\epsilon^{d-1}} \epsilon^{V^{d-1}(i, j)} + g(\epsilon),$$

$$\forall t \in [N/\epsilon^{d-1}, 1/\epsilon^d], \quad (3.1)$$

where $\chi_i = 0$, if $i \in R^{d-1}$ and $\chi_i = 1$, otherwise. (The upper bound in (3.1) is also valid for $t \in [1/\epsilon^{d-1}, N/\epsilon^{d-1}]$.) In particular, there exist $D_1, D_2 > 0, g \in \mathcal{U}$ such that

$$D_1 \epsilon^{V^d(i, j)} \leq p_{ij}(\frac{1}{\epsilon^d}) \leq D_2 \epsilon^{V^d(i, j)} + g(\epsilon). \quad (3.2)$$

We continue with a few remarks on the quantities computed by Algorithm II.

Proposition 3.2: (i) For any d, i, j , we have $V^d(i, j) \leq V^d(i, k) + V^d(k, j)$.

(ii) For any d , we have $R^{d+1} \subset R^d$.

(iii) $V^d(i, j) + V^c(j, k) \geq V^{\max\{c, d\}}(i, k)$, $\forall i, j, k, c, d$.

Proof: (i) This is an immediate consequence of part (iii) of Proposition 2.2.

(ii) Suppose that $i \in R^{d+1}$. Then, $V^{d+1}(i, i) = 0$. Using part (ii) of Proposition 2.2, we conclude that $i \notin TR^d$, or, equivalently, $i \in R^d$.

(iii) Using Proposition 3.1 twice, there exist constants D_1, D_2 such that

$$D_1 \epsilon^{V^d(i, j) + V^c(j, k)} \leq p\left(x\left(\frac{1}{\epsilon^d} + \frac{1}{\epsilon^c}\right) = k \mid x(0) = i\right) \leq D_2 \epsilon^{V^{\max\{c, d\}}(i, k)}.$$

Moreover, this inequality is true for all $X \in \mathcal{M}_\epsilon$ and for all $\epsilon > 0$. Letting ϵ be arbitrarily small, we conclude that the claimed result holds. •

As a corollary of Proposition 3.2 we conclude that some of the upper bounds of Proposition 3.1 are true even for times smaller than $1/\epsilon^{d-1}$.

Corollary 3.1: If $i \in R^d$, or if $j \in R^d$, or if $V^d(i, j) \leq V^c(i, j)$, $\forall c \leq d$, then there exists some $C > 0$ such that

$$p_{ij}(t) \leq C \epsilon^{V^d(i, j)}, \quad \forall t \in [0, 1/\epsilon^d], \quad \forall X \in \mathcal{M}_\epsilon, \quad \forall \epsilon > 0. \quad (3.3)$$

Proof: If $i \in R^d$, then $V^d(i, i) = 0$. For any $c \leq d$, and for any j , we may apply part (iii) of Proposition 3.2 to obtain $V^d(i, j) \leq V^d(i, i) + V^c(i, j) = V^c(i, j)$. A similar argument leads to the same conclusion if $j \in R^d$. Now, given some $t \leq 1/\epsilon^d$, find some c such that $t \in [1/\epsilon^{c-1}, 1/\epsilon^c]$. We then use Proposition 3.1 to obtain $p_{ij}(t) \leq D \epsilon^{V^c(i, j)} \leq D \epsilon^{V^d(i, j)}$. •

Inequality (3.3) is in general false if its assumption fails to hold.

We continue with a few remarks on the applicability and usefulness of Algorithms I and II.

Looking back at Algorithm I, we see that in order to determine $V(i, j)$ for $i \in R$ and $j \in R$, we only need to know the coefficients α_{ij} for i and j belonging to R . This has the following implication for Algorithm II: in order to compute the coefficients $\{V^{d+1}(i, j): i, j \in R^d\}$, we only need to know the coefficients $\{V^d(i, j): i, j \in R^d\}$. Since $R^{d+1} \subset R^d$, it follows that the coefficients $\{V^{d+1}(i, j): i, j \in R^{d+1}\}$ may be computed from the coefficients $\{V^d(i, j): i, j \in R^d\}$. Thus, if we are only interested in determining which states are recurrent for each time scale (as well as in determining the corresponding ergodic decomposition) we may eliminate, at each stage of Algorithm II, the states which have been found to be transient, that is the elements of TR^d . This observation, together with the fact that we only need to carry out the algorithm for just one representative from each class R_i^d , should result in a substantial amount of savings, were the algorithm to be implemented.

Algorithm II is also applicable to continuous time Markov chains. For example, let there be given a stationary (for simplicity) Markov chain whose generator A_ϵ is a polynomial in ϵ and where ϵ is an unspecified positive parameter. Then, the transition probabilities, over a time interval of unit duration, satisfy inequalities (2.1), (2.2) for a suitable choice of α_{ij} . (In fact, the α_{ij} 's may be read-off from the Taylor series expansion of e^{A_ϵ} , or, equivalently by solving a shortest path problem; the details are omitted.) Moreover, it can be shown that these coefficients α_{ij} automatically satisfy assumption (2.3), so that Propositions 2.3 and 3.1 may be applied to the discrete time Markov chain obtained by sampling the continuous time Markov chain at integer times. Finally, an elementary argument shows that the estimates obtained are valid for non integer times as well.

We compare Algorithm II and Proposition 3.1 to the results available in the literature. There has been a substantial amount of research on singularly perturbed stationary Markov chains [1,2,3,4,12]. Typical results obtain exact asymptotic expressions for the transition probabilities, as a small parameter ϵ converges to zero. These asymptotic expressions are obtained recursively, by proceeding from one time scale to the next one, similarly with Algorithm II. Each step in this recursion involves the solution of systems of linear equations and, possibly, the evaluation of the pseudoinverse of some matrices [1], which may be computationally demanding, especially if we are dealing with large scale systems. However, we may conceive of situations in which we are not so much interested in knowing the values of the transition probabilities, but rather we want to know which events are likely to occur (over a certain time interval) and which events have asymptotically negligible probability (as ϵ goes to zero). For the latter case, a non-numerical, graph-theoretic, method is more natural. Such a method (for stationary Markov chains) is implicit and easy to extract from the results of [12]. Algorithm II also accomplishes the same.

On the more technical side, it does not follow from the literature, neither is it a priori obvious, that there exist integer coefficients $V^d(i, j)$ such that inequalities of the type (3.1) hold. The existing results provide approximations for those transition probabilities which do not vanish as ϵ approaches zero [1,2,3,4,12] but much less is known about the asymptotic behavior of the vanishing transition probabilities. Furthermore, the techniques which are usually employed are tailored to stationary Markov chains (e.g. perturbation theory of linear operators) and do not seem applicable to the analysis of non-stationary chains. The discussion following Proposition 2.1 suggests one method for applying results for stationary chains to non-stationary ones but it does not seem to be universally applicable. Let us also point out that Proposition 3.1 is fairly easy to derive for "nearly decomposable" Markov chains [3]. This is not the case for more general Markov chains; in

particular, the existence of transient states which feed into different ergodic classes are the main source of difficulty [12].

IV. COOLING SCHEDULES FOR SIMULATED ANNEALING.

In simulated annealing [6,10] we are given a set $S = \{1, \dots, N\}$ of states together with a cost function $J: S \rightarrow \mathcal{N}$ to be minimized. (Our restriction that J takes integer values is not significant.) The algorithm jumps randomly from one state to another and forms a Markov chain with the following transition probabilities:

$$P(x(t+1) = j | x(t) = i) = Q(i, j) \exp[\min\{0, -(J(j) - J(i))/T(t)\}], \quad \text{if } j \neq i, \quad (4.1)$$

$$P(x(t+1) = i | x(t) = i) = 1 - \sum_{j \neq i} P(x(t+1) = j | x(t) = i), \quad (4.2)$$

where the kernel $Q(i, j)$ is nonnegative and satisfies $\sum_j Q(i, j) = 1$ and $T(t) > 0$ is the "temperature" at time t . It is known that if $T(t)$ decreases to zero slowly enough, then $x(t)$ converges (in probability) to the set at which J is minimized [5-9,11]. We are interested in determining how slowly $T(t)$ must converge to zero, so that convergence to the minimizing states is obtained. This issue has been resolved by Hajek [9] under some restrictions on the structure of $Q(i, j)$. We shall derive shortly the answer to this question in a more general setting. Moreover our method establishes a connection between simulated annealing and the structure of singularly perturbed stationary Markov chains.

We formulate the problem to be studied in a slightly more general manner, as follows. Suppose that we are given, a stochastic matrix P^ϵ , (whose ij -th entry is denoted by p_{ij}^ϵ) parameterized by a positive parameter ϵ and assume that there exist positive constants C_1, C_2 and a collection $\mathcal{A} = \{\alpha_{ij}: 1 \leq i, j \leq N\}$ such that $\alpha_{ij} \in \mathcal{N}_0 \cup \{\infty\}$, $\forall i, j$ and such that $p_{ij}^\epsilon = 0$, whenever $\alpha_{ij} = \infty$ and $C_1 \epsilon^{\alpha_{ij}} \leq p_{ij}^\epsilon \leq C_2 \epsilon^{\alpha_{ij}}$, $\forall \epsilon \in (0, 1]$, whenever $\alpha_{ij} < \infty$. Finally, we are given a function (cooling schedule) $\epsilon: \mathcal{N}_0 \rightarrow (0, 1)$. We are interested in the Markov chain $x(t)$ with transition probabilities given by $P(x(t+1) = j | x(t) = i) = p_{ij}^{\epsilon(t)}$.

Clearly, the simulated annealing algorithm is of the type described in the preceding paragraph, provided that we identify $\epsilon(t)$ with $e^{-1/T(t)}$ and provided that we define $\alpha_{ij} = \infty$, if $Q(i, j) = 0$, $i \neq j$, and $\alpha_{ij} = \max\{0, J(j) - J(i)\}$, if $Q(i, j) \neq 0$, $i \neq j$. Also, α_{ii} has to be accordingly defined.

We now return to our general formulation. We thus assume that \mathcal{A}, C_1, C_2 are given, together with the schedule $\{\epsilon(t)\}$. We assume that \mathcal{A} satisfies (2.3) and we define, for any $d \in \mathcal{N}_0$, the quantities $V^d(i, j)$ and the sets R^d by means of Algorithm II of Section III. Our main result is the following.

Proposition 4.1: Assume that for some integer $d \geq 0$,

$$\sum_{t=0}^{\infty} \epsilon^d(t) = \infty, \quad (4.3)$$

$$\sum_{t=0}^{\infty} \epsilon^{d+1}(t) < \infty. \quad (4.4)$$

Then,

(i) $\lim_{t \rightarrow \infty} P(x(t) \in R^d | x(0) = i) = 1, \quad \forall i.$

(ii) For any $i \in R^d$, $\limsup_{t \rightarrow \infty} P(x(t) = i | x(0) = i) > 0.$

Proof: The main idea of the proof is to partition $[0, \infty)$ into a set of disjoint time intervals $[t_k, t_{k+1})$ such that $x(t)$ is approximately stationary during each such interval, in the sense of Section II, and then use the estimates available for such Markov chains.

The proof for the case $d = 0$ is rather easy and is omitted. We present the comparatively harder proof for the case $d \geq 1$.

We start with the proof of part (i) of the proposition. We define $t_0 = 0$ and

$$t_{k+1} = t_k + \frac{1}{\epsilon^{d-1}(t_k)}, \quad \text{if } \epsilon\left(t_k + \frac{1}{\epsilon^{d-1}(t_k)}\right) \geq \frac{1}{2}\epsilon(t_k), \quad (4.5)$$

$$t_{k+1} = \max\{t: \epsilon(t) \geq \frac{1}{2}\epsilon(t_k)\}, \quad \text{otherwise.} \quad (4.6)$$

(If t_{k+1} as defined above turns out to be non-integer, we may assume that it is truncated to the first integer below it.) We define A_L (respectively, A_S) as the set of all k 's such that t_{k+1} is defined by (4.5) (respectively, (4.6)). We will need the following properties of the sequence $\{\epsilon(t_k)\}$.

Lemma 4.1:

$$\frac{1}{2}\epsilon(t_k) \leq \epsilon(t) \leq \epsilon(t_k), \quad \forall t \in [t_k, t_{k+1}] \quad (4.7)$$

$$\sum_{k \in A_L} \epsilon(t_k) = \infty, \quad (4.8)$$

$$\sum_{k=0}^{\infty} \epsilon^2(t_k) < \infty \quad (4.9)$$

Let $f(k, l)$ be the cardinality of $A_L \cap \{l, \dots, k-1\}$, for $k \geq l$. Then, for any $C \in (0, 1)$,

$$\sum_{k=0}^{\infty} \sum_{l=0}^k (1-C)^{f(k,l)} \epsilon(t_k) \epsilon(t_l) < \infty \quad (4.10)$$

$$\lim_{k \rightarrow \infty} \sum_{l=0}^k (1-C)^{f(k,l)} \epsilon(t_l) = 0, \quad \forall C \in (0, 1). \quad (4.11)$$

Proof: Inequalities (4.7) are an immediate consequence of (4.5), (4.6).

We notice that for any $k \in A_S$, $k' \in A_S$, with $k' > k$, we have $\epsilon(t_{k'}) \leq (1/2)\epsilon(t_k)$. Hence,

$$\sum_{k \in A_S} \epsilon(t_k) \leq \epsilon(0) \sum_{k=0}^{\infty} 2^{-k} < \infty. \quad (4.12)$$

Finally,

$$\begin{aligned}\sum_{k \in A_L} \epsilon(t_k) &= \sum_{k \in A_L} \epsilon^d(t_k)[t_{k+1} - t_k] = \sum_{k=0}^{\infty} \epsilon^d(t_k)[t_{k+1} - t_k] - \sum_{k \in A_S} \epsilon^d(t_k)[t_{k+1} - t_k] \geq \\ &\sum_{t=0}^{\infty} \epsilon^d(t) - \sum_{k \in A_S} \epsilon(t_k) = \infty,\end{aligned}$$

which proves (4.8).

From (4.12) we conclude that $\sum_{k \in A_S} \epsilon^2(t_k) < \infty$. Also,

$$\sum_{k \in A_L} \epsilon^2(t_k) = \sum_{k=0}^{\infty} \epsilon^{d+1}(t_k)[t_{k+1} - t_k] \leq 2^{d+1} \sum_{t=0}^{\infty} \epsilon^{d+1}(t) < \infty,$$

which proves (4.9).

Given any $C \in (0, 1)$, we define a constant a by $[2(1-C)]^a = 3/2$, if $2(1-C) \geq 1$; otherwise, we let $a = 1$. Let $B = \{(k, l): k \geq l \text{ and } f(k, l) \geq a(k-l)\}$. Then,

$$\sum_{(k,l) \in B} (1-C)^{f(k,l)} \epsilon(t_k) \epsilon(t_l) \leq \sum_{k=0}^{\infty} \sum_{l=0}^k [(1-C)^a]^{k-l} \epsilon(t_k) \epsilon(t_l) < \infty,$$

because $(1-C)^a < 1$ and $\epsilon(k)$ is square summable, by (4.9). Now notice that $\epsilon(t_k) \leq 2^{-(k-l)+f(k,l)} \epsilon(t_l)$, if $k \geq l$. Hence,

$$\begin{aligned}\sum_{(k,l) \notin B, k \geq l} (1-C)^{f(k,l)} \epsilon(t_k) \epsilon(t_l) &\leq \sum_{(k,l) \notin B, k \geq l} [2(1-C)]^{f(k,l)} 2^{-(k-l)} \epsilon^2(t_l) \leq \\ &\sum_{k \geq l} (3/2)^{k-l} (1/2)^{k-l} \epsilon^2(t_l) < \infty,\end{aligned}$$

which proves (4.10). The proof of (4.11) is similar and is omitted. •

We now define

$$S_0 = R^d = \{i: \text{if } V^d(i, j) = 0 \text{ then } V^d(j, i) = 0\},$$

$$S_{n+1} = \{i \in R^{d-1}: i \notin S_0 \cup \dots \cup S_n \text{ and } \exists j \in S_n \text{ such that } V^{d-1}(i, j) = 1\},$$

$$T_0 = \{i \in TR^{d-1}: \exists j \in S_0 \text{ such that } V^{d-1}(j, i) = 1\}$$

and we let T_1 be the complement of T_0 in TR^{d-1} . Notice that $(\cup_{n \geq 0} S_n) \cup T_0 \cup T_1 = \{1, \dots, N\}$. Also, if $i \in S_n$, $n \neq 0$ and $V^{d-1}(i, j) = 0$, then $j \in R_i^{d-1}$ and $j \in S_n$. (For a proof of this fact, if $i \in S_n$, then $i \in R^{d-1}$; so, if $V^{d-1}(i, j) = 0$, then $V^{d-1}(j, i) = 0$ and therefore $j \in R_i^{d-1}$. Let $l \in S_{n-1}$ be such that $V^{d-1}(i, l) = 1$. Then, $V^{d-1}(j, l) = 1$. So, either $j \in S_n$ and we are done,

or $j \in S_0 \cup \dots \cup S_{n-1}$. In the second case, the same argument shows that $i \in S_0 \cup \dots \cup S_{n-1}$ which is a contradiction.)

We let $y(k) = x(t_k)$. We need estimates on the transition probabilities of the $y(k)$ process. These are obtained by noting that, for any k , the Markov chain $\{x(t): t \in [t_k, t_{k+1}]\}$ belongs to $M_{\epsilon(t_k)}(A, 2^{-K}C_1, C_2, 0)$, where $K = \max\{\alpha_{ij}: \alpha_{ij} < \infty\}$. Since $t_{k+1} - t_k \leq 1/(\epsilon^{d-1}(t_k))$, Corollary 3.1 may be used to obtain upper bounds. Also, for $k \in A_L$, $t_{k+1} - t_k = 1/(\epsilon^{d-1}(t_k))$ and therefore Proposition 3.1 may be used to obtain lower bounds. In more detail, we have:

Lemma 4.2: There are constants $F > 0$, $G > 0$, such that, for every $k \in \mathcal{N}_0$ we have

$$(i) \text{ If } k \in A_L, \text{ then } P(y(k+1) \in S_n | y(k) \in S_{n+1}) \geq F\epsilon(t_k), \forall n. \quad (4.13)$$

$$(ii) P(y(k+1) \notin S_n | y(k) \in S_n) \leq G\epsilon(t_k), \forall n. \quad (4.14)$$

$$(iii) P(y(k+1) \notin S_0 \cup T_0 | y(k) \in S_0) \leq G\epsilon^2(t_k). \quad (4.15)$$

$$(iv) P(y(k+1) \notin S_0 \cup T_0 | y(k) \in T_0) \leq G\epsilon(t_k). \quad (4.16)$$

$$(v) P(y(k+1) \in T_0 | y(k) \in S_0) \leq G\epsilon(t_k). \quad (4.17)$$

$$(vi) \text{ If } k \in A_L, \text{ then } P(y(k+1) \in S_0 | y(k) \in T_0) \geq F. \quad (4.18)$$

$$(vii) \text{ If } k \in A_L, \text{ then, for all } i, P(y(k+1) \in TR^{d-1} | y(k) = i) \leq 1 - F. \quad (4.19)$$

Proof: (i) If $i \in S_{n+1}$, then (by definition) there is some $j \in S_n$ such that $V^{d-1}(i, j) = 1$. The result follows from the lower bound in (3.2).

(ii) Let $i \in S_n$, $j \notin S_n$. We have shown earlier that we must have $V^{d-1}(i, j) \geq 1$ and the result follows from (3.3).

(iii) Let $i \in S_0$ and $j \notin S_0 \cup T_0$. If $j \in S_n$, $n \neq 0$, then $j \notin R^d$; hence $V^d(i, j) \geq 1$. Therefore, using the definition of V^d , we have $1 \leq V^d(i, j) \leq V^d(i, i) + V^{d-1}(i, j) - 1 = V^{d-1}(i, j) - 1$. Hence $V^{d-1}(i, j) \geq 2$. Finally, if $j \in T_1$, then $V^{d-1}(i, j) \geq 2$, because otherwise we would have $j \in T_0$. The result follows from (3.3).

(iv) Let $i \in T_0$ and $j \notin S_0 \cup T_0$. Let us also choose some $l \in S_0$ such that $V^{d-1}(l, i) = 1$ (which exists by the definition of T_0). If $j \in S_n$, $n \neq 0$, then $V^{d-1}(i, j) \geq 1$, because otherwise $V^{d-1}(l, j) = 1$, which contradicts the discussion in the proof of part (iii). So, for this case the result follows from (3.3). Suppose now that $j \in T_1$. For any $c \leq d-1$ we must have $V^c(i, j) \geq 1$ because otherwise (using Proposition 3.2) $V^{d-1}(l, j) \leq V^{d-1}(l, i) + V^c(i, j) = 1$, which contradicts the assumption $j \in T_1$. The result follows again from (3.3).

(v) This is immediate from $V^{d-1}(i, j) \geq 1, \forall i \in R^{d-1}, \forall j \in TR^{d-1}$ (Proposition 2.2, part (ii)).

(vi) Let $i \in T_0$. Since $i \in TR^{d-1}$, there exists some $j \in R^{d-1}$ such that $V^{d-1}(i, j) = 0$. By the previous discussion, such a j cannot belong to S_n , for $n \geq 1$. The result follows from (3.2).

(vii) Similarly, for any i there exists some $j \in R^{d-1}$ such that $V^{d-1}(i, j) = 0$ and the result follows from (3.2). •

Let

$$H_k = P(y(n) \in S_0 \cup T_0, 0 \leq n \leq k | y(0) \in S_0),$$

$$Q_k = P(y(k) \in T_0 | y(n) \in S_0 \cup T_0, 0 < n \leq k-1, y(0) \in S_0).$$

Using (4.17), (4.18), we obtain

$$Q_{k+1} \leq G\epsilon(t_k) + (1 - \chi_k F)Q_k,$$

where $\chi_k = 1$ if $k \in A_L$ and $\chi_k = 0$, otherwise. So,

$$Q_k \leq G \sum_{l=0}^k \epsilon(t_l) (1 - F)^{j(k,l)}.$$

Using (4.15), (4.16),

$$H_{k+1} \geq [1 - G\epsilon(t_k)Q_k - G\epsilon^2(t_k)]H_k \quad (4.20)$$

Now, $\epsilon(t_k)Q_k$ is summable, by (4.10); also, $\epsilon^2(t_k)$ is summable, by (4.9). Hence $\liminf_{k \rightarrow \infty} H_k > 0$. More intuitively, once the state enters S_0 , there is positive probability that it never leaves $S_0 \cup T_0$. Consequently, the total flow of probability into S_0 from S_1 must be finite. Hence, using (4.13), we have

$$\sum_{k=0}^{\infty} \epsilon(t_k) P(y(k) \in S_1) < \infty.$$

We will prove by induction that for all $n \geq 1$,

$$\sum_{k=0}^{\infty} \epsilon(t_k) P(y(k) \in S_n) < \infty. \quad (4.21)$$

Using (4.13), (4.14), we have

$$P(y(k+1) \in S_n) \geq P(y(k) \in S_n) - G\epsilon(t_k)P(y(k) \in S_n) + \chi_k F\epsilon(t_k)P(y(k) \in S_{n+1}). \quad (4.22)$$

By telescoping the inequality (4.22) and using the induction hypothesis (4.21), we see that $\sum_{k=0}^{\infty} \chi_k \epsilon(t_k) P(y(k) \in S_{n+1}) < \infty$. Also, $\sum_{k \in A_S} \epsilon(t_k) P(y(k) \in S_n + 1) \leq \sum_{k \in A_S} \epsilon(t_k) < \infty$ (because of (4.12)) which completes the induction step. Using (4.21) and the fact that $\epsilon(t_k)$ sums to infinity we conclude that $\limsup_{k \rightarrow \infty} P(y(k) \in S_0 \cup TR^{d-1}) = 1$. We show next that the probability

of transient states goes to zero. Inequalities (4.14) and (4.19) imply

$$P(y(k+1) \in TR^{d-1}) \leq G\epsilon(t_k) + (1 - \chi_k F)P(y(k) \in TR^{d-1}).$$

Thus,

$$P(y(k+1) \in TR^{d-1}) \leq (1 - F)^{f(k,0)} + G \sum_{l=0}^k (1 - F)^{f(k,l)} \epsilon(t_l),$$

which converges to 0, as k tends to infinity, due to (4.11). We may thus conclude that $\limsup_{k \rightarrow \infty} P(y(k) \in S_0) = 1$. By repeating the argument that led to (4.20) we can see that the probability that y ever exits $S_0 \cup T_0$, given that $y(k) \in S_0$, converges to zero, as $k \rightarrow \infty$. (This is a consequence of the square summability of $\epsilon(t_k)$.) It follows that $\lim_{k \rightarrow \infty} P(y(k) \in S_0) = 1$. Finally, for any $t \in [t_k, t_{k+1}]$ we have $P(x(t) \in S_0) \geq P(y(k) \in S_0) - G\epsilon(t_k)$, which converges to 1, as $k \rightarrow \infty$. This completes the proof of part (i) of the proposition.

For part (ii) of the proposition, in order to avoid introducing new notation, we prove the equivalent statement that if $\sum_{t=0}^{\infty} \epsilon^d(t) < \infty$, then $\limsup_{t \rightarrow \infty} P(x(t) = i | x(0) = i) > 0$, $\forall i \in R^{d-1}$. So, let $i \in R^{d-1}$ and consider the set R_i^{d-1} . For any $j \notin R_i^{d-1}$, we have $V^{d-1}(i, j) \geq 0$ and, therefore, (using Corollary 3.1), there exists some $G > 0$ such that

$$P(y(k+1) \notin R_i^{d-1} | y(k) \in R_i^{d-1}) \leq G\epsilon(t_k), \quad \forall k.$$

Since we are assuming that $\sum_{t=0}^{\infty} \epsilon^d(t) < \infty$, it follows (as in the proof of (4.9)), that $\sum_{k=0}^{\infty} \epsilon(t_k) < \infty$. Consequently,

$$\inf_k P(y(k) \in R_i^{d-1} | y(0) = i) > 0. \quad (4.23)$$

Finally, for any $j \in R_i^{d-1}$ we have $V^{d-1}(j, i) = 0$. Hence, using Proposition 3.1, there exists some $F > 0$ such that

$$P(y(t_{k+1}) = i | y(t_k) \in R_i^{d-1}) \geq F. \quad (4.24)$$

By combining (4.23), (4.24), we obtain the desired result. •

Corollary 4.1: Let the transition probabilities for the simulated annealing algorithm be given by (4.1), (4.2). Consider cooling schedules of the form $T(t) = c/\log t$. The smallest constant c such that, for any initial state, the algorithm converges (in probability) to the set of global minima of J , equals the smallest d such that the set of global minima contains R^d .

Proof: Let d^* be the smallest such d . Having identified $\exp[-1/T(t)]$ with $\epsilon(t)$, we see that the algorithm converges appropriately if and only if $\sum_{t=1}^{\infty} \exp[-d^* \log t/c] = \infty$. Equivalently, $\sum_{t=1}^{\infty} t^{(-d^*/c)} = \infty$, which is equivalent to $d^* \leq c$. •

Proposition 4.1 can be applied to any continuous time simulated annealing algorithm, because in that case we may sample the Markov chain at integer times and condition (2.3) will be automatically true. For discrete time algorithms, even if (2.3) fails, the result is still valid for any structure \mathcal{A} such that the estimates (2.8) of Proposition 2.3 are true (with an appropriate choice of $V(i, j)$). We have seen in Section II that this is the case for a much broader class of Markov chains. In fact, we conjecture that Proposition 4.1 is always true, provided that the sets R^d are correctly defined.

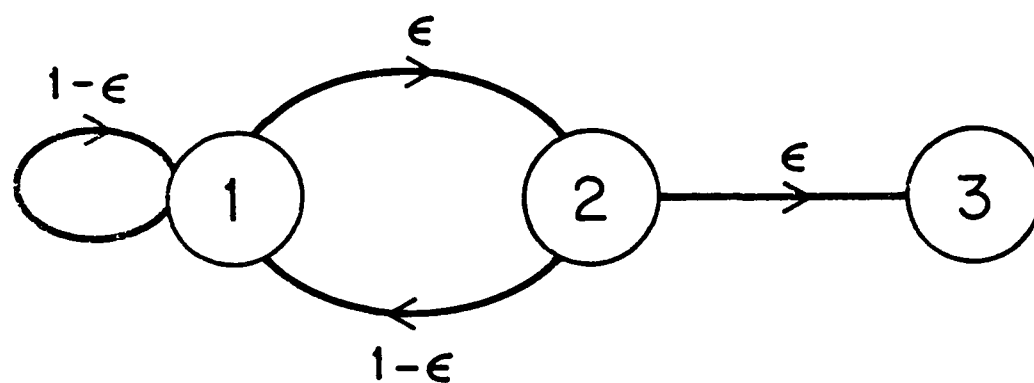

Another possibility for generalizing Proposition 4.1 comes by allowing the schedule $\epsilon(t)$ to be non-monotonic. In fact the proof goes through (with a minor modification in the definition of the sequence $\{t_k\}$) if we only assume that there exists some $C > 0$ such that $\epsilon(t) \leq C\epsilon(s)$, $\forall t \geq s$, which allows for mild non-monotonicity. On the other hand, if $\epsilon(t)$ is allowed to have more substantial variations, then the conclusions of Proposition 4.1 are no more true. For a simple example consider the Markov chain of Figure 1, together with the schedule $\epsilon(t) = t^{-1/2}$, if t is even, and $\epsilon(t) = 1/t$, if t is odd. For this schedule, the largest integer for which $\sum_{t=0}^{\infty} \epsilon^d(t) = \infty$ is equal to 2. Also, $R^2 = \{3\}$. On the other hand, $P(x(t) = 3 | x(0) = 1)$ does not converge to 1.

We have claimed that our result generalizes the results of [9] and we end the paper by supporting this claim. Hajek's result characterized d^* in an explicit manner, as the maximum depth¹ of local minima which are not global minima, under a "weak reversibility" assumption, which is equivalent to imposing certain restrictions on the structure \mathcal{A} . Our characterization is less explicit because instead of describing d^* we give an algorithm for computing it in terms of \mathcal{A} . Nevertheless, for the class of structures \mathcal{A} considered in [9], we can use our Algorithm II to show that R^d is the set of all local minima of the cost function J , of depth $d + 1$, or more. Hence, the d^* produced by our algorithm is the smallest d such that all local (but not global) minima have depth d or less, which agrees with the result of [9]. We do not present the details of this argument since it would amount to rederiving a known result.

1. The depth of a state i is defined as the minimum over all j , such that $J(j) < J(i)$, of the minimum over all paths leading from i to j , of the maximum of $J(k) - J(i)$, over all k 's belonging to that path; the depth of i is infinite if no such j exists.
